II. FIXED POINT THEORY OF OVER-SCREENED MCK MODEL

A. RG flows towards intermediate coupling

We start with the usual K -channel Kondo model Hamiltonian with isotropic couplings [1]:

$$H_l = \sum_k \sum_{\alpha=\uparrow,\downarrow} \epsilon_{k,l} \hat{n}_{k\alpha,l} + \mathcal{J} \sum_{kk'} \sum_{\alpha,\beta=\uparrow,\downarrow} \vec{S}_d \cdot \frac{1}{2} \vec{\sigma}_{\alpha\alpha'} c_{k\alpha,l}^\dagger c_{k'\alpha',l},$$

$$H = \sum_{l=1}^K H_l. \quad (1)$$

Here, l sums over the K channels of the conduction bath, k, k' sum over all the momentum states of the bath and α, β sum over the two spin indices of a single electron. \mathcal{J} is the Kondo spin-exchange coupling. $c_{k\alpha,l}$ is the fermionic field operator at momentum k , spin α and channel l . $\epsilon_{k,l}$ represents the dispersion of the l^{th} conduction channel. $\vec{\sigma}$ is the vector of Pauli matrices and $\vec{S}_d = \frac{1}{2} \vec{\sigma}_d$ is the impurity spin operator.

We have performed a renormalisation group analysis of the Hamiltonian using the recently developed URG method [2–7]. The RG proceeds *by applying unitary transformations in order to block-diagonalize the Hamiltonian by removing number fluctuations of the high energy degrees of freedom*. If the most energetic electronic state at the j^{th} RG step is $|j\rangle$ defined by the energy $D_{(j)}$, the Hamiltonian will in general not conserve the number of particles in this state: $[H_{(j)}, \hat{n}_j] \neq 0$. The unitary transformation $U_{(j)}$ will remove this number fluctuation at the next RG step:

$$H_{(j-1)} = U_{(j)} H_{(j)} U_{(j)}^\dagger, \quad [H_{(j-1)}, \hat{n}_j] = 0 \quad (2)$$

The unitary transformations are given in terms of a fermionic generator $\eta_{(j)}$:

$$U_{(j)} = \frac{1}{\sqrt{2}} \left(1 + \eta_{(j)} - \eta_{(j)}^\dagger \right), \quad \left\{ \eta_{(j)}, \eta_{(j)}^\dagger \right\}_\pm = 1 \quad (3)$$

where $\{A, B\}_\pm = AB \pm BA$. The generator itself is given by the expression

$$\eta_{(j)}^\dagger = \frac{1}{\hat{\omega}_{(j)} - \text{Tr}(H_{(j)} \hat{n}_j)} c_j^\dagger \text{Tr}(H_{(j)} c_j) \quad (4)$$

The operator $\hat{\omega}_{(j)}$ encodes the quantum fluctuation scales arising from the interplay of the kinetic energy terms and the interaction terms of the Hamiltonian:

$$\hat{\omega}_{(j)} = H_{(j-1)} - H_{(j)}^i \quad (5)$$

$H_{(j)}^i$ is that part of $H_{(j)}$ that commutes with \hat{n}_j but does not commute with at least one \hat{n}_l for $l < j$. The RG continues up to energy D^* where a fixed point is reached from the vanishing of either the numerator or the denominator.

The derivation of the RG equation for the over-screened regime ($2S < K$) of the spin- S -impurity K -channel Kondo problem is shown in the supplementary materials. On decoupling circular isoenergetic shells at energies $D_{(j)}$, the change in the Kondo coupling at the j^{th} RG step, $\Delta\mathcal{J}_{(j)}$, is given by

$$\Delta\mathcal{J}_{(j)} = -\frac{\mathcal{J}_{(j)}^2 \mathcal{N}_{(j)}}{\omega_{(j)} - \frac{D_{(j)}}{2} + \frac{\mathcal{J}_{(j)}}{4}} \left(1 - \frac{1}{2}\rho\mathcal{J}_{(j)}K\right) \quad (6)$$

$\mathcal{N}_{(j)}$ is the number of electronic states at the energy shell $D_{(j)}$. We work in the low quantum fluctuation regime $\omega_{(j)} < \frac{D_{(j)}}{2}$. There are three fixed points of the RG equation. One arises from the vanishing of the denominator, and was present in the single-channel Kondo RG equation as well [8]. As shown there, this fixed-point goes to $\mathcal{J}^* = \infty$ as the bare bandwidth of the conduction electrons is made large. The other trivial fixed point is the trivial one at $\mathcal{J}^* = 0$. The third fixed point is reached when the numerator vanishes: $\mathcal{J}^* = \frac{2}{K\rho}$ [1, 9–11]. Only the intermediate fixed point is found to be stable. This is consistent with results from Bethe ansatz calculations [12–17], CFT calculations [18–20], bosonization treatments [21, 22] and NRG analysis [23, 24].

FIG. 1. The three fixed points of the over-screened RG equation. Only the intermediate one is stable.

The RG equation reduces to the perturbative form $\Delta\mathcal{J}_{(j)} \simeq \frac{\mathcal{J}_{(j)}^2 \mathcal{N}_{(j)}}{D_{(j)}} \left(1 - \frac{1}{2}\rho\mathcal{J}_{(j)}K\right)$ [1, 10, 11, 25] when one replaces $\omega_{(j)}$ with the ground state energy $-\frac{D_{(j)}}{2}$ and assumes $\mathcal{J} \ll D_{(j)}$.

B. Star graph as the effective fixed point Hamiltonian

The fixed point Hamiltonian takes the form

$$H^* = \sum_l \left[\sum_k^* \epsilon_{k,l} \hat{n}_{k\alpha,l} + \mathcal{J} \sum_{kk'}^* \vec{S}_d \cdot \frac{1}{2} \vec{\sigma}_{\alpha\alpha'} c_{k\alpha,l}^\dagger c_{k'\alpha',l} \right] \quad (7)$$

We have not explicitly written the decoupled degrees of freedom $D_{(j)} > D^*$ in the Hamiltonian. The $*$ over the summations indicate that only the momenta inside the window D^* enter the summation. There is an implied summation over the spin indices α, β .

To study the low energy physics and universality of the problem, we will mostly focus on the zero bandwidth limit of the fixed point Hamiltonian. Upon setting the chemical potential equal to the Fermi energy, this zero

bandwidth model becomes a Heisenberg spin-exchange Hamiltonian.

$$H^* = \mathcal{J} \sum_l \sum_{kk'}^* \vec{S}_d \cdot \frac{1}{2} \vec{\sigma}_{\alpha\alpha'} c_{k\alpha,l}^\dagger c_{k'\alpha',l} = \mathcal{J} \vec{S}_d \cdot \sum_l \vec{s}_l \quad (8)$$

At the last step, we defined the local spin operator $\vec{s}_l = \frac{1}{2}\sigma_l = \frac{1}{2} \sum_{kk'}^* \sum_{\alpha\beta} \vec{\sigma}_{\alpha\alpha'} c_{k\alpha,l}^\dagger c_{k'\alpha',l}$ of each conduction channel. The star graph commutes with several op-

FIG. 2. Zero bandwidth limit of the fixed point Hamiltonian. The central yellow node is the impurity spin, which is talking with K green outer nodes that represent the local spins of the channels.

erators, including the total spin operator $J^z = S_d^z + \sum_l s_l^z$ along z , the total bath local spin operator $s_{\text{tot}}^2 = (\sum_l \vec{s}_l)^2$ and the string operators

$$\pi^{x,y,z} = \sigma_d^{x,y,z} \otimes_{l=1}^K \sigma_l^{x,y,z} \quad (9)$$

The π^z acts on the eigenstates $|J^z\rangle$ and reveals the odd-even parity of the eigenvalue J^z , and is hence a parity operator. Interestingly, the string operator π^z is a Wilson loop operator [26] that wraps around all the nodes of the star graph:

$$\pi^z = \exp \left[i \frac{\pi}{2} \left(\sigma_d^z + \sum_{l=1}^K \sigma_l^z - K \right) \right] = e^{i\pi(J^z - \frac{1}{2}K)} \quad (10)$$

π^x and π^y mix states of opposite parity. For example, it can be shown that $\pi^x |J^z\rangle = -|J^z\rangle$. These are 't Hooft operators [26].

There are multiple reasons for working with the star graph in particular and zero mode Hamiltonians in general. In the single-channel Kondo model, the star graph is just the two spin Heisenberg, and it reveals the stabilization of the Kondo model ground state, as well as certain thermodynamic properties (e.g., the impurity contribution to the susceptibility) [8, 27–30]. Similarly in the MCK model, the star graph is able to mimic the nature of the RG flows: At weak coupling $\mathcal{J} \rightarrow 0^+$, the central spin is weakly coupled to the outer spins and prone to screening because of the s^\pm terms in the star graph, and at strong coupling $\mathcal{J} \rightarrow \infty^-$, the outer spin-half objects tightly bind with the central spin-half object to form a single spin object that interacts with the remaining states through an exchange coupling which is RG relevant, rendering both the terminal fixed points unstable. The true stable fixed point must then lie somewhere in between, and we recover the schematic phase diagram of fig. 1.

The utility of the star graph is due to the fact that the non-Fermi liquid arises solely from the degeneracy of the ground state manifold of the underlying zero mode Hamiltonian, and the star graph captures this degeneracy in its entirety. The RG flows of the MCK model have been shown to preserve the degeneracy of the ground state [23, 31, 32]. The star graph conserves the total spin J^z , and this leads to a ground state degeneracy of $|\frac{K}{2} - S| + 1$ in the K -channel spin- S star graph which is preserved under the RG flow. This is qualitatively different from the case of the single-channel Kondo model where the 2-fold degeneracy of the local moment fixed point crosses over into a stable and unique singlet ground state.

As we will see in a subsequent section, the lowest excitations of the intermediate fixed point is described a non-Fermi liquid phase induced by nearest-neighbour hopping terms between the zeroth sites and the first sites of the conduction channels. The importance of the degeneracy can be shown in the following manner. As mentioned previously, the ground state degeneracy of the more general star graph with a spin- S impurity and K channels is given by $g_K^S = |K - 2S| + 1$. The cases of $K = 2S$, $K < 2S$ and $K > 2S$ correspond to exactly screened, under-screened and over-screened regimes respectively. *The latter two cases correspond to a multiply-degenerate manifold $g_K^S > 1$, and simultaneously have non-Fermi liquid phases [1, 9, 12, 18, 19, 21, 33-43], while the first regime has a unique ground state $g_K^S = 1$ and is described by a local Fermi liquid (LFL) phase [1, 44-47], thereby substantiating the claim that a degeneracy greater than unity leads to non-Fermi liquid physics.* In the following sections, we will show how the inherent quantum-mechanical frustration of singlet order that is present in the Hamiltonian leads to the degenerate ground state manifold and the non-trivial physics of the fixed points in terms of non-Fermi liquid phase, diverging thermodynamic quantities, quantum criticality as well as emergent gauge theories.

III. IMPORTANT PROPERTIES OF THE STAR GRAPH

A. Hamiltonian and wavefunctions

As shown in the previous section, at the heart of multi channel Kondo there is a stargraph problem which is the zero mode of the lowenergy fixed point Hamiltonian of the Multi channel Kondo. In this section our focus will be on the stargraph problem itself. As shown in the Fig.2 above one central spin (\vec{S}_d) is connected with K spins forming a K channel stargraph problem corresponding to the K -channel Kondo problem. The Hamiltonian of this above model is given as

$$H = \mathcal{J} \vec{S}_d \cdot \sum_{i=1}^K \vec{S}_i = \mathcal{J} \vec{S}_d \cdot \vec{S}$$

$$= \frac{\mathcal{J}}{2} (\vec{J}^2 - \vec{S}^2 - \vec{S}_d^2), \quad \mathcal{J} > 0. \quad (11)$$

where $\vec{J} = \vec{S} + \vec{S}_d$ and $\vec{S} = \sum_{i=1}^K \vec{S}_i$. One can see that the large spin S can take many possible values as this is made out of K spin $1/2$ s. We can see $[H, J] = 0 = [H, J^i]$ for $i = x, y, z$, $[J^i, J^j] \neq 0$ for $i \neq j$. In our model we find two string operators $\hat{\mathbb{Z}} = \sigma_d^z \prod_{i=1}^K \sigma_i^z$ and $\hat{\mathbb{X}} = \sigma_d^x \prod_{i=1}^K \sigma_i^x$, where K is the number of channels. These two operators commutes with the Hamiltonian H of this stargraph.

$$[H, \hat{\mathbb{Z}}] = 0 = [H, \hat{\mathbb{X}}] \quad (12)$$

We can rewrite the operators in the form of a twist operator as, $\mathbb{Z} = e^{i\pi[J^z - (\frac{K+1}{2})]}$ and $\mathbb{X} = e^{i\pi[J^x - (\frac{K+1}{2})]}$. The commutation between these two operators are given as

$$[\mathbb{Z}, \mathbb{X}] = \prod_{i=d,1}^K \sigma_i^z \prod_{i=d,1}^K \sigma_i^x \left[1 - (-1)^{K+1} \right] \quad (13)$$

MERGE THIS WITH EARLIER SUBSECTION.

Thus we can see that for case where number of channels is odd that means $K + 1$ is even, these two string operators commutes with each other forming a CSCO ($H, \mathbb{Z}, \mathbb{X}$). On the other hand in the case where number of channels K is even, these two operators does not commute with each other. Thus we can form the CSCO with H, J, J^z, S, S_d . For a particular value S , J can take two values $S \pm S_d$ with the energies $-\mathcal{J}S_d(S_d + 1 \mp J)$ respectively. S_d is fixed thus the energy values only depends on the corresponding J value of the state. As the energy does not depends on the J^z , all $2J + 1$ J^z states labeled by $|S_d, S; J, J^z\rangle$ are degenerate. It is easy to see that the ground state has energy $E = -\mathcal{J}S_d(S_d + 1 + J)$ with $J = S - S_d$, thus $E_g = -\mathcal{J}S_d(S_{max} + 1)$ with S taking the maximum possible value $S_{max} = K/2$.

B. Degree of compensation: a measure of the frustration

One can quantify the amount of screening of the local moment at the impurity site by defining a degree of compensation κ . Such a quantity also measures the inherent singlet frustration in the problem: the higher the degree of compensation, the better the spin can be screened into a singlet and lower is the frustration. It is given by the antiferromagnetic correlation existing between the impurity spin and conduction electron channels:

$$\Gamma \equiv -\langle \vec{S}_d \cdot \vec{s}_{\text{tot}} \rangle \quad (14)$$

where $\vec{s}_{\text{tot}} = \sum_l \vec{s}_l$. The expectation value is calculated in the ground state. Since the inner product is simply the ground state energy of a spin- S impurity K -channel MCK model in units of the exchange coupling J , we have

$$\Gamma = \frac{1}{2} [l_{\text{imp}}^2 + l_c^2 - g_K^S (g_K^S - 1)] \quad (15)$$

$l_{\text{imp}}^2 = S(S+1)$ is the length-squared of the impurity spin. Similarly, $l_c^2 = \frac{K}{2}(\frac{K}{2} + 1)$ is the length-squared of the total conduction bath spin. $g_K^S = |\frac{K}{2} - S| + 1$ is the ground state degeneracy. We will explore the three regimes of screening by defining $K = K_0 + \delta$, $S = \frac{K_0}{2} - \delta$. $\delta = 0$ represents the exactly-screened case of $K = 2S = K_0$. Non-zero δ represents either over- or under-screening. In terms of K_0 and δ , the degree of compensation becomes

$$\Gamma = \frac{1}{4} \left[(K_0 + 1)^2 - (|\delta| + 1)^2 \right] \quad (16)$$

For a given K_0 , the degree of compensation is maximised for exact screening $\delta = 0$, and is reduced for $\delta \neq 0$. This shows the inability of the system to form a unique singlet ground state and reveals the quantum-mechanical frustration inherent in the zero mode Hamiltonian and therefore in the entire problem. The degree of compensation is symmetric under the Hamiltonian transformation $\delta \rightarrow -\delta$, and this represents a duality transformation between over-screened and under-screened MCK models. This topic will be discussed in more detail later.

FIG. 3. Variation of the degree of compensation as we tune the system from under-screening to over-screening. The maximum spin compensation occurs at exact-screening $\delta = 0$.

C. Impurity magnetization and susceptibility

The channel isotropic MCK model is critical; any perturbation away from the perfectly symmetric model in terms of anisotropy is relevant, as shown in section VII [23, 48, 49]. This critical nature leads to several signatures that can be obtained directly from the star graph. These signatures include a discontinuity in the impurity magnetization at zero temperature in the limit of the external field going to zero, and a diverging susceptibility as temperature goes to zero.

We insert a magnetic field that acts only on the impurity and then diagonalize the Hamiltonian.

$$H(h) = J^* \vec{S}_d \cdot \vec{s}_{\text{tot}} + h S_d^z \quad (17)$$

The Hamiltonian commutes with s_{tot} , so it is already block-diagonal in terms of the eigenvalues M of s_{tot} . M takes values in the range $[M_{\text{min}}, M_{\text{max}}]$, where $M_{\text{max}} = K/2$ for a K -channel Kondo model, and $M_{\text{min}} = 0$ if K is even, otherwise $\frac{1}{2}$. Within each block, the Hamiltonian splits into independent 2×2 blocks characterized by eigenvalues of the total spin operator $J^z = S_d^z + s_{\text{tot}}^z$. Defining $\alpha = \frac{1}{2}(Jm + h) + \frac{J}{4}$ and $x_m^M = M(M+1) - m(m+1)$, the partition function can be written as

$$Z(h) = \sum_{M=M_{\text{min}}}^{M_{\text{max}}} r_M^K \left[\sum_{\substack{m=-M, \\ m \in \mathbb{Z}}}^{M-1} 2e^{\beta \frac{J}{4}} \cosh \beta \sqrt{J^2 x_m^M / 4 + \alpha^2} + 2e^{-\beta J M / 2} \cosh \beta h / 2 \right] \quad (18)$$

Here, $\beta = \frac{1}{k_B T}$, M sums over the eigenvalues of s_{tot} while m sums over $J^z - \frac{1}{2}$ and the additional degeneracy factor $r_M^K = K^{-1} C_{K/2-M}$ arises from the possibility that there are multiple subspaces defined by $s_{\text{tot}} = M$.

To calculate the impurity magnetic susceptibility, we will use the expression

$$\chi = \frac{1}{\beta} \lim_{h \rightarrow 0} \left[\frac{Z''(h)}{Z(h)} - \left(\frac{Z'(h)}{Z(h)} \right)^2 \right] \quad (19)$$

where the \prime indicates derivative with respect to h . For brevity, we define $\theta_M = \beta J(M + \frac{1}{2})/2$ and $\Sigma_M = \sum_{\substack{m=-M, \\ m \in \mathbb{Z}}}^{M-1} (m + \frac{1}{2})^2$. The derivatives are

$$\lim_{h \rightarrow 0} Z(h) = \sum_{M=M_{\text{min}}}^{M_{\text{max}}} r_M^K \left[4M e^{\beta \frac{J}{4}} \cosh \theta_M + 2e^{-\beta J M / 2} \right] \quad (20)$$

$$\lim_{h \rightarrow 0} \frac{dZ(h)}{dh} = 0 \quad (21)$$

$$\lim_{h \rightarrow 0} \frac{d^2 Z(h)}{dh^2} = \frac{\beta^2}{2} \sum_{M=M_{\text{min}}}^{M_{\text{max}}} r_M^K \left[\frac{e^{\beta \frac{J}{4}}}{\theta_M} (2M \sinh \theta_M + \frac{\beta^2 J^2}{4} \left[\frac{\cosh \theta_M}{\theta_M} - \frac{\sinh \theta_M}{\theta_M^2} \right] \Sigma_M) + e^{-\beta J M / 2} \right] \quad (22)$$

At low temperature $\beta \rightarrow \infty$, only the highest value M_{max} will survive:

$$Z \rightarrow 2r_{M_{\text{max}}}^K M_{\text{max}} e^{\beta \frac{J}{2}(M_{\text{max}}+1)} \quad (23)$$

$$Z'' \rightarrow r_{M_{\text{max}}}^K \left(\frac{\beta}{2(M_{\text{max}} + \frac{1}{2})} \right)^2 e^{\beta \frac{J}{2}(M_{\text{max}}+1)} \Sigma_{M_{\text{max}}} \quad (24)$$

$$\chi \rightarrow \frac{\beta \Sigma_{\text{max}}}{2M_{\text{max}}(2M_{\text{max}} + 1)^2} = \frac{\beta(K-1)}{12(K+1)} \sim \frac{1}{T} \quad (25)$$

This non-analyticity in a response function is a signature of the critical nature of the Hamiltonian. This is in contrast to the behaviour in the non-critical exactly-screened fixed point where the ground state is unique. There, the susceptibility becomes constant at low temperatures: $\chi(T \rightarrow 0) = \frac{W}{4T_K}$, T_K being the single-channel Kondo temperature and W the Wilson number [8, 29, 45, 50]. We have checked the case of general spin- S impurity numerically, and the general conclusion is that all exactly-screened models show a constant impurity susceptibility at $T \rightarrow 0$, while the over-screened and under-screened cases show a diverging impurity susceptibility in the same limit.

Another non-analyticity arises when we consider the impurity free energy and the magnetization. The thermal free energy is given by

$$F(h) = -\frac{1}{\beta} \ln Z(h) = -\frac{1}{\beta} \ln \sum_{E_n} e^{-\beta E_n} \quad (26)$$

At $T \rightarrow 0$, only the most negative energy E_{\min} survives. Assuming a non-degenerate ground state for $h \neq 0$, the zero temperature free energy becomes

$$F(h \neq 0, T \rightarrow 0) = -\frac{1}{\beta} \ln e^{-\beta E_{\min}} = E_{\min} \quad (27)$$

In the star graph Hamiltonian with K -channels and in the presence of a field on the impurity (eq. 17), the ground state energy will be one of the negative eigenvalues:

$$\lambda_{m,-}^{M,h} = -\frac{J}{4} - \frac{1}{2} \sqrt{J^2(M+1/2)^2 + h^2 + 2hJ(m+1/2)} \quad (28)$$

The minimum eigenvalue is obtained by maximizing $h(m+1/2)$. For $h > 0$, the ground state is renormalised for the most positive value of m , which is $M-1$. On the other hand, for $h < 0$, it occurs for $m = -M$, because that is the most negative value it can take. Among all the values of M , the global ground state is at the largest value of M , $K/2$. Therefore, the minimal energy eigenvalue is

$$E_{\min} = -\frac{J}{4} - \frac{1}{2} \sqrt{J^2(K+1)^2/4 + h^2 + |h|J(K-1)} \quad (29)$$

The first derivative of the free energy with respect to the field gives

$$F'(h \neq 0, T \rightarrow 0) = -\frac{2h + J(K-1)\text{sign}(h)}{4\sqrt{\frac{J^2}{4}(K+1)^2 + h^2 + |h|J(K-1)}} \quad (30)$$

There we used the result that the derivative of $|x|$ is $\text{sign}(x)$. If we now take h to zero from both directions, we get the magnetization of the impurity

$$m = F'(h \rightarrow 0^\pm, T \rightarrow 0) = \mp \frac{1}{2} \frac{(K-1)}{(K+1)} \quad (31)$$

FIG. 4. Behaviour of the impurity magnetization for three values of $(K, 2S) = (2, 4), (3, 3), (4, 2)$. Only the case of $K = 2S = 3$ ($\delta = 0$) is analytic near zero. The non-analyticity of the other cases arises because of the frustration brought about by the degeneracy of the star graph ground state.

The magnetization is therefore discontinuous as $h \rightarrow 0$; it goes to different values depending on the direction in which we take the limit. The non-analyticity for $K > 1$ occurs because there is at least one pair of ground state with non-zero parity π^z and magnetic field is able to flip one ground state into the state of opposite parity. This available space for scattering is simply the frustration that we discussed earlier. This argument, along with the diverging susceptibility for the over- and under-screened cases, makes it clear that *the non-analyticity and hence the critical nature of the fixed point arise because of the ground state degeneracy, and is therefore a feature of all over-screened and under-screened models*. Indeed, we have checked numerically (see fig. 4) that the non-analyticity exists for $\delta \neq 0$, where $\delta = \frac{K}{2} - S$ is the deviation from exact screening. For $\delta = 0$, the ground state is unique and un-frustrated, so the external magnetic field has no parity-inverted pair to flip across.

MERGE WITH ABOVE Here we want to calculate the field susceptibility of the stargraph. For that we need the entire spectrum of the stargraph Hamiltonian in the presence of field. There are two ways one can capture the susceptibility of the stargraph, first, by putting a small field to the central impurity and the other way is put a uniform field on all the outer spins and capture the susceptibility.

Impurity-field susceptibility : Now we add small magnetic field to the impurity spin and calculate the susceptibility as a function of temperature for different channel cases. As shown in the Figure.5 above, for all $K > 2$ case we can see that, at low temperature the susceptibility follows power law as a function of temperature.

$$\chi_{\text{imp}}(T) \sim T^{-1}, \quad \chi_{\text{outer}} \sim T^{-1} \quad (32)$$

The exponent for all the channels $K > 2$ is -1 . This shows the presence of an universality class. The powerlaw

FIG. 5. Impurity susceptibility vs temperature.

shows the critical nature of the system.

Outer-field susceptibility: Similar study can be done by putting an uniform field on all outer spins and calculating the susceptibility. Here also for all channels $K > 2$ the exponent is -1 and supports the existence of universality and criticality. This susceptibility clearly shown the

FIG. 6. Outer susceptibility vs temperature.

breakdown of screening in the multichannel cases with degenerate ground states in contrast to the single channel susceptibility which saturates at a finite value at low temperature.

D. Topological properties of ground state manifold

We can define two operators, for convenience let's call translation and twist operator respectively, \hat{T} and \hat{O} defined as

$$\hat{T} = e^{i\frac{2\pi}{K}\hat{\Sigma}}, \quad \hat{O} = e^{i\hat{\phi}}, \quad \hat{\Sigma} = [\hat{J}^z - (K-1)/2] \quad (33)$$

One can see that the generators of these above operators commutes with the Hamiltonian, $[H, J^x] = [H, J^z] = [H, J^y] = 0$. In the large channel limit we can do semiclassical approximation. As J^x and J^y both commutes

with the Hamiltonian H then $[H, J^y(J^x)^{-1}] = 0$, and any non-singular function of these operators must also commute with the Hamiltonian, thus we can say that

$$\hat{\phi} = \tan^{-1}(\hat{J}^y(\hat{J}^x)^{-1}) \quad (34)$$

Then we get $[\hat{\phi}, \hat{H}] = 0$. We can label the ground states by the eigen values of the translation operator \hat{T} . We can also use the ground states labeled by the eigenvalues of J^z (M , say). Then the ground states are

$$|M_1\rangle, |M_2\rangle, |M_2\rangle, \dots, |M_K\rangle \quad (35)$$

Then the operations of the translation operators on this states are give below.

$$\hat{T}|M_i\rangle = e^{i\frac{2\pi}{K}[M_i - (K-1)/2]}|M_i\rangle = e^{i2\pi\frac{p_i}{K}}|M_i\rangle, \quad p_i \in [K] \quad (36)$$

Now we check the braiding rule between the twist and the translation operators, we find

$$\begin{aligned} \hat{T}\hat{O}\hat{T}^\dagger\hat{O}^\dagger &= e^{\frac{2\pi}{K}[i\hat{\Sigma}, i\hat{\phi}]} = e^{i\frac{2\pi}{K}} \\ \hat{T}\hat{O}^m\hat{T}^\dagger\hat{O}^{\dagger m} &= e^{\frac{2\pi}{K}[i\hat{\Sigma}, im\hat{\phi}]} = e^{i2\pi\frac{m}{K}} \end{aligned} \quad (37)$$

Next we shown that the states $\hat{O}^m|M_i\rangle$ are orthogonal to each other and with the state $|M_i\rangle$.

$$\begin{aligned} \hat{T}\hat{O}^m|M_i\rangle &= \hat{O}^m\hat{T}e^{i2\pi\frac{m}{K}}|M_i\rangle = \hat{O}^me^{i\frac{2\pi(m+p_i)}{K}}|M_i\rangle \\ \hat{T}\left(\hat{O}^m|M_i\rangle\right) &= e^{i\frac{2\pi(m+p_i)}{K}}\left(\hat{O}^m|M_i\rangle\right) \end{aligned} \quad (38)$$

Thus different states $\hat{O}^m|M_i\rangle$ for different m are labeled by different eigenvalues of the translation operations, thus are orthogonal to each other. Now as the twist operator \hat{O} commutes with the Hamiltonian, thus we can see that

$$\langle M_i|\hat{O}^{m\dagger}H\hat{O}^m|M_i\rangle = \langle M_i|H|M_i\rangle \quad (39)$$

Thus the energy eigen values of all the orthogonal states are equal. Thus all the K mutually orthogonal states are degenerate.

E. Local Mott liquid

Using the unitary renormalization group method we decouple the impurity spin from the zero-modes of the K channels. We start with the Hamiltonian. The zero mode Hamiltonian is a stargraph model

$$\begin{aligned} H &= \mathcal{J}\vec{S}_d \cdot \sum_i \vec{S}_i = \mathcal{J}S_d^z S^z + \frac{\mathcal{J}}{2}(S_d^+ S^- + S_d^- S^+) \\ H_D &= \mathcal{J}S_d^z S^z, \quad H_X = \frac{\mathcal{J}}{2}(S_d^+ S^- + S_d^- S^+) \end{aligned} \quad (40)$$

Here we want to remove the quantum fluctuations between the impurity spin and the rest, for that we do one step URG.

$$\Delta H = H_X \frac{1}{\hat{\omega} - H_D} H_X \quad (41)$$

In the zero mode IR fixed point ground state (stargraph) of multi-channel ground state J^z is a good quantum number but S^z is not. There is no net S^z field thus in the ground state manifold the average S^z is vanishing, $\langle S^z \rangle = 0$. We use this expectation value to replace the denominator of the above RG equation.

$$\beta_{\uparrow}(\mathcal{J}, \omega_{\uparrow}) = \frac{\mathcal{J}^2 \Gamma_{\uparrow}}{2}, \quad \Gamma_{\uparrow} = \frac{1}{\omega_{\uparrow} - \mathcal{J}(S_d^z - 1)} \quad (42)$$

Thus we get the effective Hamiltonian is

$$\begin{aligned} H_{eff} &= \frac{\mathcal{J}^2 \Gamma_{\uparrow}}{2} (S^2 - S^{z2}) (\tau_d^2 - \tau_d^z) \\ &= \frac{\beta_{\uparrow}(\mathcal{J}, \omega_{\uparrow})}{4} (S^+ S^- + S^- S^+) \end{aligned} \quad (43)$$

In terms of the electronics degree of freedom this looks

$$\frac{\beta_{\uparrow}(\mathcal{J}, \omega_{\uparrow})}{4} \sum_{\substack{i \neq j \\ \alpha_i, \beta_i \in \{\uparrow, \downarrow\} \\ \alpha_j, \beta_j \in \{\uparrow, \downarrow\}}} \vec{\sigma}_{\alpha_i \beta_i} \vec{\sigma}_{\alpha_j \beta_j} c_{0\alpha_i}^{(i)\dagger} c_{0\beta_i}^{(i)} c_{0\alpha_j}^{(j)\dagger} c_{0\beta_j}^{(j)} + \text{h.c.}$$

We will study the two cases of the above effective Hamiltonian depending on the sign of the prefactor. The case $\frac{\beta_{\uparrow}(\mathcal{J}, \omega_{\uparrow})}{2} > 0$ is the ferromagnetic case where in the ground state S takes the minimum value and S^z takes the possible maximum value. For an example, in the case of K channels the minimum value of S will be 0 or $1/2$ for K being *even* or *odd* respectively. We will be interested in the other case where $\frac{\beta_{\uparrow}(\mathcal{J}, \omega_{\uparrow})}{2} < 0$. In this case the ground state corresponds to S being maximum and S^z being minimum case. The effective Hamiltonian can be re-written in this case as

$$H_{eff} = -\frac{|\beta_{\uparrow}(\mathcal{J}, \omega_{\uparrow})|}{4} (S^+ S^- + S^- S^+) \quad (44)$$

The CSCO of this Hamiltonian contains H, S, S^z . In the ground state S is maximum thus $S = K/2$ and S^z can

take $2S + 1 = K + 1$ values. Thus in the largest S sector there are $K + 1$ states. One can explore different states via a flux tuning mechanism. In the presence of the flux the Hamiltonian looks like **(SHOW THE BOUNDARY CONDITION CHANGING TWIST OPERATOR THAT LEADS TO THIS FLUX)**

$$H = -\frac{|\beta_{\uparrow}(\mathcal{J}, \omega_{\uparrow})|}{2} S^2 + \frac{|\beta_{\uparrow}(\mathcal{J}, \omega_{\uparrow})|}{2} \left(S^z - \frac{\Phi}{\Phi_0} \right)^2 \quad (45)$$

SHORTEN AND MERGE WITH THE EARLIER SUBSECTION Now we are going to discuss about the mapping of K degenerate ground states of the parent K -channel stargraph model with the states of this flux-inserted all-to-all model obtained by removing impurity-bath quantum fluctuations. In the stargraph model the K ground states is labeled by the J^z eigenvalues. In the stargraph ground state $J = S - 1/2$, where S is maximum with value $S = K/2$. Thus there are $2J + 1 = K$ unique J_z eigenvalues corresponding to the J sector labeling different eigenstates. The ground state Hilbert space \mathcal{H}_{gr} contains the J^z states

$$\mathcal{H}_{gr} = \{-(K-1)/2, -(K-3)/2, \dots, (K-3)/2, (K-1)/2\} \quad (46)$$

Now we shift our focus to the low energy Hamiltonian with flux shown in the eq.(45). We can see that there is a unique ground state labeled by the S^z eigenvalues. By tuning the flux (Φ/Φ_0) one can go from one ground state to another ground state or change the ground state. We can see that ground state energy is independent of the configuration of the impurity spin ($S_d^z = \pm 1/2$). Thus for each of those two possibilities we get two set of ground states labeled by the S^z and the $J^z = S^z + S_d^z$. Similar to the stargraph case here also the ground state corresponds to the largest S sector, $S = K/2$. Thus total number of S^z eigenvalues are $2S + 1 = K + 1$ taking values $\{-K/2, -(K-2)/2, \dots, (K-2)/2, K/2\}$.

$$\begin{aligned} S_d^z = +1/2, \{J^z\} &= \{-(K-1)/2, -(K-3)/2, \dots, (K-1)/2, (K+1)/2\} \\ S_d^z = -1/2, \{J^z\} &= \{-(K+1)/2, -(K-1)/2, \dots, (K-3)/2, (K-1)/2\} \end{aligned} \quad (47)$$

Thus one can see that the ground state degeneracy of the stargraph model with different J^z values gets lifted in the quantum fluctuation resolved all-to-all model. Depending on the value of the flux there is a unique ground state labeled by the J^z value. Tuning the flux one can go from one ground state to the other. This shows how one can explore different degenerate ground states of the parent stargraph model via the insertion of flux in the corresponding quantum fluctuation resolved all-to-all effective Hamiltonian.

IV. LOCAL NON-FERMI LIQUID EXCITATIONS OF THE 2-CHANNEL KONDO

A. Effective Hamiltonian

RADICALLY SHORTEN! Here we start with the low energy zero mode fixed point Hamiltonian for the two-channel Kondo obtained under URG treatment. Our goal here is to add excitations on top of this ground state and using the perturbation theory. In doing so we consider the leading order scatter appearing in the lowest order in the perturbative expansion. Note, in the fixed

FIG. 7. This figure shows the comparison and mapping between the stargraph degenerate ground states and the states of the quantum fluctuation resolved all to all model.

point zero mode Hamiltonian impurity spin is coupled with the bath electrons via spin exchange coupling, there is no charge exchange coupling present.

$$H^{(2)} = \mathcal{J} \vec{S}_{imp} \cdot (\vec{S}_1 + \vec{S}_2) \quad , \quad \vec{S}_i = \frac{1}{2} c_{i,\alpha}^\dagger \vec{\sigma}_{\alpha,\beta} c_{i,\beta} \quad (48)$$

Here $\vec{S}_i = 1, 2$ represents the spin degree of freedom present in the origin of the i^{th} channel. Thus one can rewrite the Eq.(48) in terms of the electronic degree of freedom as,

$$\begin{aligned} \mathcal{H}_0 &= H_{01} + H_{02} \\ &= \sum_{i=\{1,2\}} \left[\mathcal{J} S_{imp}^z (n_{i,\uparrow} - n_{i,\downarrow})/2 + \frac{1}{2} (S_{imp}^+ c_{i,\downarrow}^\dagger c_{i,\uparrow} + \text{h.c.}) \right] \end{aligned}$$

Here the basis we are interested in is $\{\mathcal{B}\} = \{|S_{imp}^z, n_{1,\uparrow}, n_{1,\downarrow}, n_{2,\uparrow}, n_{2,\downarrow}\rangle\}$. In this basis we write down all $2^3 = 8$ states of the spin Hamiltonian eq.(48). First the two degenerate ground states with energy $-\mathcal{J} = E_{\alpha_0} = E_{\alpha_1}$ is given as,

$$\begin{aligned} |\alpha_0\rangle &= \frac{1}{\sqrt{6}} \left[2|\downarrow, 1, 0, 1, 0\rangle - |\uparrow, 0, 1, 1, 0\rangle - |\uparrow, 1, 0, 0, 1\rangle \right] \\ |\alpha_1\rangle &= \frac{1}{\sqrt{6}} \left[2|\uparrow, 0, 1, 0, 1\rangle - |\downarrow, 1, 0, 0, 1\rangle - |\downarrow, 0, 1, 1, 0\rangle \right] \end{aligned}$$

The doubly degenerate lowest lying excited state has energy $E_{\beta_1} = E_{\beta_2} = 0$.

$$\begin{aligned} |\beta_0\rangle &= \frac{1}{\sqrt{2}} \left[|\downarrow, 1, 0, 0, 1\rangle - |\downarrow, 0, 1, 1, 0\rangle \right] \\ |\beta_1\rangle &= \frac{1}{\sqrt{2}} \left[|\uparrow, 1, 0, 0, 1\rangle - |\uparrow, 0, 1, 1, 0\rangle \right] \quad (49) \end{aligned}$$

Above these two excited states there are another degenerate excited state manifold with energy $E_{\gamma_0} = E_{\gamma_1} = E_{\gamma_2} = E_{\gamma_3} = \frac{\mathcal{J}}{2}$.

$$\begin{aligned} |\gamma_0\rangle &= \frac{1}{\sqrt{3}} \left[|\uparrow, 0, 1, 0, 1\rangle + |\downarrow, 1, 0, 0, 1\rangle + |\downarrow, 0, 1, 1, 0\rangle \right] \\ |\gamma_1\rangle &= \frac{1}{\sqrt{3}} \left[|\uparrow, 1, 0, 0, 1\rangle + |\uparrow, 0, 1, 1, 0\rangle + |\downarrow, 1, 0, 1, 0\rangle \right] \\ |\gamma_2\rangle &= |\uparrow, 1, 0, 1, 0\rangle, \quad |\gamma_3\rangle = |\downarrow, 0, 1, 0, 1\rangle \quad (50) \end{aligned}$$

Note this spin Hamiltonian has total 8 states, where ground state is double degenerate with energy $-\mathcal{J}$ and

the lowest excited state with energy 0 is also double degenerate and the second excited state with energy $\mathcal{J}/2$ is 4-fold degenerate.

On top of the zero mode spin-channel interactions we want to consider the effect of the momentum space kinetic energy term $\sum_k \epsilon_k (n_{1,k} + n_{2,k})$. We assume identical dispersion for both the channels. Our zero mode spin Hamiltonian is written in the real space, thus it will be easier to do the perturbation theory on the real space. The Fourier transformation of the momentum space kinetic energy term leads to real space hopping term. For simplicity we will be considering the nearest neighbor hoppings between sites within each channel. The real space hopping contribution to the Hamiltonian H_X with the hopping strength is

$$H_X = -t \sum_{\langle 1, l_1 \rangle \langle 2, l_2 \rangle} (c_{1,\sigma}^\dagger c_{l_1,\sigma} + c_{2,\sigma}^\dagger c_{l_2,\sigma} + \text{h.c.}) \quad (51)$$

Here l_i represents the nearest site to the origin of the i^{th} channel. Thus here we are interested in studying the Hamiltonian $\mathcal{H}_0 + H_X$. The perturbing term H_X contains scattering which takes the states of the zero mode Hamiltonian out of spin-channel scattering space. Thus before we start the perturbation theory we must expand the basis of the zero mode Hamiltonian itself. Thus the basis which contains the nearest neighbor sites of both the channels is given as

$$\begin{aligned} \{\mathcal{B}_{extnd}\} &\equiv \{\mathcal{B}\} \otimes \{|n_{l_1,\uparrow}, n_{l_1,\downarrow}, n_{l_2,\uparrow}, n_{l_2,\downarrow}\rangle\} \\ &= \{|S_{imp}^z, n_{1,\uparrow}, n_{1,\downarrow}, n_{2,\uparrow}, n_{2,\downarrow}\rangle \otimes |n_{l_1,\uparrow}, n_{l_1,\downarrow}, n_{l_2,\uparrow}, n_{l_2,\downarrow}\rangle\} \end{aligned} \quad (52)$$

Note there are $2^4 = 16$ elements in the subspace $\{|n_{l_1,\uparrow}, n_{l_1,\downarrow}, n_{l_2,\uparrow}, n_{l_2,\downarrow}\rangle\}$. In the spin-channel basis $\{\mathcal{B}\}$ there are 2 degenerate ground states. Because the unperturbed Hamiltonian \mathcal{H}_0 has no scattering terms outside the spin sector, in the extended basis $\{\mathcal{B}_{extnd}\}$ the total ground state degeneracy becomes simply $2 \times 2^4 = 32$ fold. Thus the total Hamiltonian we are interested in is

$$\mathcal{H} = \frac{\mathcal{J}\hbar}{2} \vec{S}_d \cdot \sum_{i=\{1,2\}} \sum_{\alpha,\beta \in \{\uparrow,\downarrow\}} c_{i\alpha}^\dagger \vec{\sigma}_{\alpha\beta} c_{i\alpha} + H_X \quad (53)$$

There are two degenerate states $|\alpha_1\rangle$ and $|\alpha_2\rangle$. Thus the two degenerate ground states in the above basis are given as,

$$|\tilde{\alpha}_0\rangle = |\alpha_0\rangle \otimes |n_{l_1,\uparrow}, n_{l_1,\downarrow}, n_{l_2,\uparrow}, n_{l_2,\downarrow}\rangle \quad (54)$$

$$|\tilde{\alpha}_1\rangle = |\alpha_1\rangle \otimes |n_{l_1,\uparrow}, n_{l_1,\downarrow}, n_{l_2,\uparrow}, n_{l_2,\downarrow}\rangle \quad (55)$$

Using degenerate perturbation theory we calculate the first and the second order corrections to the Hamiltonian. The first order and the second order low energy effective Hamiltonian is given as

$$\begin{aligned} H^{(1)} &= \sum_{ij} |\alpha_i\rangle \langle \alpha_i| V |\alpha_j\rangle \langle \alpha_j| \\ H^{(2)} &= \sum_{ij} \sum_l |\alpha_i\rangle \frac{\langle \alpha_i| V |\mu_l\rangle \langle \mu_l| V |\alpha_j\rangle}{E_0 - E_l} \langle \alpha_j| \quad (56) \end{aligned}$$

where $|\alpha_i\rangle$ represents the ground states with energy E_0 and μ_l represents the excited states with energy E_l . One can easily check the diagonal term in effective Hamiltonian coming from the 1st or any *odd* order correction is zero as the state never returns to the original starting state via odd number of scatterings. For the case of first order it is easy to see that the off-diagonal correction to the effective Hamiltonian is also zero. Thus the lowest order where we expect the non-zero corrections is the second order. We first calculate the diagonal correction in the first order

$$H_{diag}^{(2)} = \sum_i \sum_l |\alpha_i\rangle \langle \alpha_i| \frac{|\langle \alpha_i | V | \mu_l \rangle|^2}{E_0 - E_l} \quad (57)$$

As single scattering always takes the state outside of the spin-channel, the state $V|\alpha_i\rangle$ is an excited state with energy 0 ($= E_l$). This α_i representing the ground state can take total 32 configurations as discussed. Out of this 32 states $|\alpha_0\rangle \otimes |n_{l_1,\uparrow}, n_{l_1,\downarrow}, n_{l_2,\uparrow}, n_{l_2,\downarrow}\rangle$ can take 16 configurations and $|\alpha_1\rangle \otimes |n_{l_1,\uparrow}, n_{l_1,\downarrow}, n_{l_2,\uparrow}, n_{l_2,\downarrow}\rangle$ can take the rest 16 configurations. Note the two degenerate states $|\tilde{\alpha}_0\rangle$ and $|\tilde{\alpha}_1\rangle$ is labeled by the J^z eigenvalue $\pm 1/2$ respectively, where J^z is the total z-component of the impurity and zero modes of the baths. Thus these 32 ground states can be separated in two 16 state groups labeled by the $J^z = \pm 1/2$ eigenvalues. For the $J^z = 1/2$ sector we get the effective Hamiltonian

$$H_{diag}^{(2)}(1/2) = \frac{2t^2}{E_0} \hat{I} - \frac{2t^2}{3E_0} (S_{l_1}^z + S_{l_2}^z) \quad (58)$$

Similarly the for $J^z = -1/2$ we get

$$H_{diag}^{(2)}(-1/2) = \frac{2t^2}{E_0} \hat{I} + \frac{2t^2}{3E_0} (S_{l_1}^z + S_{l_2}^z) \quad (59)$$

where $S_{l_i}^z = (n_{l_i,\uparrow} - n_{l_i,\downarrow})/2$. This above result shows that the diagonal correlation to the LEH coming from the ground states $J^z = \pm 1/2$ has a emergent field term.

$$H_{diag}^{(2)} = -4t^2 \hat{I} \quad (60)$$

But the total contribution shows the trivial nature of the diagonal part in the LEH. This clearly shown that there is no Fermi liquid terms present in low energy in the 2-channel Kondo problem. Here, \hat{I} is the identity operator made out of all $2^4 = 16$ possible number operator combinations as shown below

$$\hat{I} = \sum_{\hat{\sigma}=\hat{n},(1-\hat{n})} \hat{\sigma}_{l_1,\uparrow} \hat{\sigma}_{l_1,\downarrow} \hat{\sigma}_{l_2,\uparrow} \hat{\sigma}_{l_2,\downarrow} \quad (61)$$

Due to the ground state degeneracy in the 2-channel problem, there are possible quantum scattering within the ground state manifold among those degenerate states. This leads to a low energy effective Hamiltonian which is offdiagonal in nature as shown below,

$$H_{NFL} = H_{off}^{(2)} = \sum_{i \neq j} \sum_l |\alpha_i\rangle \frac{\langle \alpha_i | V | \mu_l \rangle \langle \mu_l | V | \alpha_j \rangle}{E_0 - E_l} \langle \alpha_j |$$

$$= -\frac{8t^2}{3} [(S_1^z)^2 c_{2\uparrow}^\dagger c_{2\downarrow} (c_{l_1\uparrow}^\dagger c_{l_1\downarrow}^\dagger + c_{l_2\uparrow}^\dagger c_{l_2\downarrow}^\dagger) + (S_2^z)^2 c_{1\uparrow}^\dagger c_{1\downarrow} (c_{l_1\uparrow}^\dagger c_{l_1\downarrow}^\dagger + c_{l_2\uparrow}^\dagger c_{l_2\downarrow}^\dagger)] + \text{h.c.}, \quad (62)$$

This LEH is purely a non-Fermi liquid. The emergence of non-Fermi liquid is primarily coming due to the degenerate ground states present in the stargraph problem in the absence of the realspace hopping terms. One can see that though there was no prior inter channel direct interactions, the LEH shows the emergence of such terms through correlated quantum scatterings. **MENTION THAT WE HAVE COMPUTED VARIOUS THERMODYNAMIC QUANTITIES THAT ARE IN FAIR AGREEMENT WITH THE LITERATURE. AND THAT THESE ARE SHOWN IN THE SUPPLEMENTARY MATERIALS. ALSO MENTION THAT WE HAVE ALSO DERIVED AN EFFECTIVE HAMILTONIAN FOR THE THREE CHANNEL CASE, ALSO SHOWN IN SUPPLEMENTARY MATERIALS.**

B. Local Marginal Fermi liquid and Orthogonality catastrophe

At the stable fixed point $J^* = J_1^* = \frac{2}{K\rho}$, the ground states of the Hamiltonian are those of the star graph model, with a degeneracy of K . We now specialise to the two-channel Kondo model. To find the low-energy excitations on top of this ground state manifold, we insert a tight-binding nearest-neighbour hopping between the zeroth site (the one that holds the impurity) and the first site (site that's nearest to the zeroth site) as a perturbation and calculate the diagonal and off-diagonal terms generated by this perturbation. It is found that when we trace out the impurity, we are left only with real space off-diagonal terms:

$$V_{\text{eff}} = \frac{2t^2}{J^*} \left[(\sigma_{0,1}^z)^2 s_{0,2}^+ + (\sigma_{0,2}^z)^2 s_{0,1}^+ \right] (s_{1,1}^- + s_{1,2}^-) + \text{h.c.} \quad (63)$$

where $\sigma_{0,l}^z = \hat{n}_{0\uparrow,l} - \hat{n}_{0\downarrow,l}$, $s^+ = c_{0\uparrow,l}^\dagger c_{0\downarrow,l}$ and $s^- = (s^+)^\dagger$. The notation $0\sigma, l$ has the site index $i = 0, 1, 2, \dots$ as the first label, the spin index $\sigma = \uparrow, \downarrow$ as the second label and the channel index $l = 1, 2$ as the third index.

These are the terms that are generated because of the presence of the impurity. Such a non-Fermi liquid (NFL) contribution to the effective Hamiltonian and the absence of any Fermi-liquid term at the same order should be contrasted with the local Fermi liquid excitations induced by the singlet ground state of the single-channel Kondo model [29, 45, 51]. We wish to point out that such NFL terms were also obtained by Coleman, et al. [39] in terms of Majorana fermions at the zeroth site and the first site of the $\sigma - \tau$ version of the two-channel Kondo model. They then went on to compute a single-particle self-energy renormalisation coming from this NFL term

that matches the phenomenological [52] and microscopic forms of the marginal Fermi liquid self-energy [3, 53]. We take a different route in order to calculate the self-energy contribution coming from Eq. 63.

In the URG analysis of the 2D Hubbard model at half-filling [3], it was found that the normal phase of the Mott insulator was a metal with properties that have been phenomenologically attributed to the marginal Fermi liquid. The excitations of such a phase are described by a two particle-one hole composite object:

$$H_{\text{MFL}} = \sum_{k,k',k'',\sigma} R \hat{n}_{k\sigma} \hat{n}_{k'\bar{\sigma}} (1 - \hat{n}_{k''\sigma}) \quad (64)$$

We wish to look for such a term in the effective Hamiltonian. For this, we will perform a perturbative treatment of the hopping at strong coupling $J \rightarrow \infty$ where the perturbative coupling t^2/J is arbitrarily small and again obtain Eq. 63. Such a change from the strong coupling model with parameter J to a weak coupling model with parameter t^2/J amounts to a duality transformation [31, 32]. It can be shown that the duality transformation leads to an identical MCK model [31] (self-duality), which implies we can have identical RG flows, and our transformation simply extracts the NFL piece from the dual model. The self-duality also ensures that the critical intermediate-coupling fixed point is unique and can be reached from either of the models.

The diagonal part of eq. 63 is

$$V_{\text{eff}} = \frac{2t^2}{J} \sum_{l=1,2} \left(\sum_{\sigma} \hat{n}_{0\sigma,l} \right) s_{0,\bar{l}}^+ s_{1,\bar{l}}^- + \text{h.c.} \quad (65)$$

where $\bar{l} = 3 - l$ is the channel index complementary to l . We will Fourier transform this effective Hamiltonian into k -space. The NFL part becomes

$$\sum_{\sigma, \{k_i, k'_i\}, l} \frac{2t^2}{J} e^{i(k_1 - k'_1)a} c_{k\sigma,l}^\dagger c_{k'\sigma,l} c_{k_2\uparrow,\bar{l}}^\dagger c_{k_2\downarrow,\bar{l}} c_{k_1\downarrow,\bar{l}}^\dagger c_{k'_1\uparrow,\bar{l}} + \text{h.c.} \quad (66)$$

This form of the Hamiltonian is very similar to the three-particle interaction term in Appendix B of [53]. The channel indices in Eq. 66 can be mapped to the normal directions in [53]. As speculated earlier, the 2 particle-1 hole interaction in Eq. 66 has a diagonal component which can be obtained by setting $k = k', k_1 = k'_2$ and $k_2 = k'_1$:

$$\begin{aligned} H_{\text{eff,MFL}} &= \sum_{\substack{k,k_1, \\ k_2,\sigma,l}} \frac{2t^2 e^{i(k_1 - k_2)a}}{J} \hat{n}_{k\sigma,l} \hat{n}_{k_2\uparrow,\bar{l}} (1 - \hat{n}_{k_1\downarrow,\bar{l}}) + \text{h.c.} \\ &= \sum_{\substack{k,k_1, \\ k_2,\sigma,l}} \frac{4t^2}{J} \cos a(k_1 - k_2) \hat{n}_{k\sigma,l} \hat{n}_{k_2\uparrow,\bar{l}} (1 - \hat{n}_{k_1\downarrow,\bar{l}}) \end{aligned} \quad (67)$$

The most dominant contribution comes from $k_1 = k_2 =$

k' , revealing the non-Fermi liquid metal [15, 38]:

$$H_{\text{eff,MFL}}^* = \frac{4t^2}{J} \sum_{\sigma,k,k',l} \hat{n}_{k\sigma,l} \hat{n}_{k'\uparrow,\bar{l}} (1 - \hat{n}_{k'\downarrow,\bar{l}}) \quad (68)$$

Following [53], one can follow the RG evolution of the dual coupling $R_j = \frac{4t^2}{J_j}$ at the j^{th} RG step, in the form of the URG equation

$$\Delta R_j = - \frac{R_j^2}{\omega - \epsilon_j/2 - R_j/8} \quad (69)$$

In the RG equation, ϵ_j represents the energy of the j^{th} isoenergetic shell. It is seen from the RG equation that R is relevant in the range of $\omega < \frac{1}{2}\epsilon_j$ that has been used throughout, leading to a fixed-point at $R^*/8 = \omega - \frac{1}{2}\epsilon^*$. The relevance of R is expected because the strong coupling J is irrelevant and $R \sim 1/J$.

The renormalisation in R leads to a renormalisation in the single-particle self-energy [53]. The k -space-averaged self-energy renormalisation is

$$\Delta\Sigma(\omega) = \rho R^{*2} \int_0^{\epsilon^*} \frac{d\epsilon_j}{\omega - \epsilon_j/2 + R_j/8} \quad (70)$$

The density of states can be approximated to be N^*/R^* , where N^* is the total number of states over the interval R^* . As suggested by the fixed point value of R_j , we can approximate its behaviour near the fixed point by a linear dependence of the dispersion ϵ_j . The two limits of the integration are the start and end points of the RG. We start the RG very close to the Fermi surface and move towards the fixed point ϵ^* . Near the start point, we substitute $\epsilon = 0$ and $R = \omega$, following the fixed point condition. From the the fixed point condition, we also substitute $R^*/8 = \omega - \frac{1}{2}\epsilon^*$. On defining $\bar{\omega} = N^*(\omega - \frac{1}{2}\epsilon^*)$, we can write

$$\Delta\Sigma(\omega) \sim \bar{\omega} \ln \frac{N^*\omega}{\bar{\omega}} \quad (71)$$

The self-energy also provides the quasiparticle residue for each channel[53]:

$$Z(\bar{\omega}) = \left(2 - \ln \frac{2\bar{\omega}}{N^*\omega} \right)^{-1} \quad (72)$$

As the energy scale $\omega \rightarrow 0$, the Z vanishes, implying that the ground state and lowest-lying excitations, in the presence of the NFL terms, are not adiabatically connected to the Fermi gas. This is the orthogonality catastrophe [52, 54-56] in the two-channel Kondo problem, and it is brought about by the presence of the terms in Eq. 68. Such terms were absent in the single-channel Kondo model, because there was no multiply-degenerate ground state manifold that allowed scattering. This line of argument shows that the extra degeneracy of the ground state subspace and the frustration of the singlet order that comes about when one upgrades from the

single-channel Kondo model to the MCK models is at the heart of the NFL behaviour, and the orthogonality catastrophe should be a general feature of all such frustrated MCK models. A local NFL term with a self-energy of the form in eq. 71 was also obtained in the $\sigma - \tau$ model by Coleman et al. [39]. The common features show the universality between the two-channel Kondo and the $\sigma - \tau$ models.

V. ENTANGLEMENT PROPERTIES

MINIMISE THE WORDS RADICALLY!

A. Entanglement properties of the star graph

Using the above exact wavefunctions we can numerically compute various entanglement properties of this star-graph model.

1. Impurity entanglement entropy

FIG. 8. Caption

Here we are interested in finding the entanglement of the central impurity spin with the rest of the multi-channel bath zero mode. For single channel case the ground state is unique and is $|J = 0, J_z = 0\rangle = \frac{1}{\sqrt{2}}(|\uparrow_d \downarrow_0\rangle - |\downarrow_d \uparrow_0\rangle)$. Thus, one can easily calculate the reduced density matrix of the impurity by tracing out the 0^{th} state. From that reduced density matrix the entanglement entropy is $\log 2$, which is maximum possible for a spin-1/2. In the case of multi-channel problem there are K orthogonal set of ground states $|J^z\rangle$, for each such state the entanglement is different. The state $|J^z\rangle \equiv |S_d = 1/2, S = K/2; (S - 1/2), J^z\rangle$ can be written in the fundamental basis. Then the density matrix is $\rho = |J^z\rangle\langle J^z|$ from which we can calculate the reduced density matrix by partial tracing the impurity degree of

freedom

$$\rho_d = \text{Tr}_d \rho = \sum_{S_d^z} \langle S_d^z | \rho | S_d^z \rangle, \quad EE_d = -\rho_d \log \rho_d \quad (73)$$

The eigenvalues of this reduced density matrix given by λ_i is called entanglement spectrum. We are interested in the von-Neumann entanglement entropy of the impurity spin with the rest (EE_d). We are interested in the scaling of this entanglement entropy with the channel number. As shown in the Fig.8 the x-axis is the channel number and for a particular channel there are many possible entanglement values corresponding to different J^z states. The minimum entanglement entropy state (associated with the $J^z = J$ state) decreases showing the classical nature of this maximally polarized state. On the other hand the maximum entanglement entropy (associated with J_{min}^z state) for a particular channel K is saturating to $\log K$ in the large K limit. Another important result that we see, for any odd value of K the minimum entanglement entropy associated with $J^z = 0$ is $\log 2$ shows a formation of perfectly entangled state made out of more than 2 spins (e.g; singlet). In this state $|J^z = 0\rangle$ all the K (odd) outer spins participate in quantum scattering with the central impurity spin in such a way the central spin is maximally entangled which is not the case for any other J^z state. In the large K limit irrespective of its even and odd nature there are always a J_{min}^z state where the central impurity spin is maximally entangled. In a K channel system all

FIG. 9. caption

the outer spins are equivalent (has Z_N symmetry), thus studying the entanglement of any one outer spin with the rest is enough. Here we do a similar entanglement entropy study where we get the reduced density matrix (ρ_o) by partial tracing out any one outer spin say the l^{th} ($1 \leq l \leq K$) one S_l^z .

$$\rho_o = \text{Tr}_l \rho = \sum_{S_l^z} \langle S_l^z | \rho | S_l^z \rangle, \quad EE_o = -\rho_o \log \rho_o \quad (74)$$

We do a similar entanglement scaling with the channel number K . We find that minimum entanglement entropy associated with the state $J^z = J$ is approaching zero in the limit $K \gg 1$. In contrast the minimum entanglement

entropy associated with J_{min}^z state is saturating at $\log 2$ in the large K . Thus in the state $J^z = 0$ for any K (or $J^z = \pm 1/2$ for $K \gg 1$) any outer spin is maximally entangled with the rest.

The above entanglement studies Fig.(8,9) show that for odd channel case there exist a state $J^z = 0$ where the central spin S_d and any outer spin S_i is maximally entangled with the rest. This shows the special and unique property of the stargraph ground state where you can create state made out of more than 2 spins where each any every one is maximally entangled with the rest. Thus this stargraph ground state is very important in the quantum information theory.

2. Mutual Information

FIG. 10. ds

In the above study our focus was on the von-Neumann entanglement entropy, now we are interested in the correlation signatures present in the stargraph ground states. Mutual information is one such measure which captures the correlations present between two subsystems (A,B) in a particular state defined as

$$I^2(A : B) = S_A + S_B - S_{A \cup B} \quad (75)$$

where S_A is the von-Neumann entanglement entropy of the subsystem A with the rest. Here we are interested in computing two types of mutual informations first, study the mutual information between the impurity-spin and one outer spin $I^2(d : o)$. Because all the outer spins are symmetric, the mutual information between impurity-spin with any one outer spin is same and can capture the correlation between two A and B . We have done a scaling study of this mutual information for different channel numbers K . As shown in the Fig.10 in the large K limit the maxima of the mutual information associated with the state J_{min}^z is saturating at 0.3748 and the Mutual information associated with the state $J^z = J$ is decreasing showing the classical limit. Next, we have done a similar study by calculating the mutual information between two outer spin $I^2(o : o)$. In this also we find that the maximum mutual information between any

FIG. 11. ds

outer spins saturates at the value 0.3759 very close to the $I^2(d : o)$ case.

As can be seen from the above Figure.(10,11) that both the maximum mutual information of $I^2(d : o)$ and $I^2(o : o)$ try to saturate near the same value. Thus in the large K limit in the J_{min}^z state mutual information between any two spins in the stargrah model is same saturating at a constant value (0.37). Though the difference can be seen in the state $J^z = J$ where the mutual information thus correlation s between two outer spins vanishes in the large K limit faster than the mutual information between the impurity and any one outer spin. Thus correlation wise there is no difference between impurity-outer pair and outer-outer pair in the large K limit.

3. Multi-partite information

Similar to the mutual inforamtion one can calculate any higher order mutli-partie inforamtion to find the nature of the correlations present in different ground states. We define the tripartite information among three subsystems A, B, C as $I_{ABC}^3 = (S_A + S_B + S_C) - (S_{AB} + S_{BC} + S_{CA}) + S_{ABC}$. This tri-parite information scaling with the number of channels K also shown behavior similar to the mutual information case, the highest tri-partite information is associated with the J_{min}^z state and saturating in the limit of $K \gg 1$. One can measure N -partite information for a collection of subsystems (CSS) $\{\mathcal{A}\} \equiv \{A_1, A_2, \dots, A_K\}$. To define the N -partite information, we first define the power set of the CSS $\{\mathcal{A}_N\}$ as $\mathcal{P}(\{\mathcal{A}_N\})$, and the collection of all subsets of $\mathcal{P}(\{\mathcal{A}_N\})$ with m subsystems in it as $\mathcal{B}_m(\{\mathcal{A}_N\}) \equiv \{Q \mid Q \subset \mathcal{P}(\{\mathcal{A}_N\}), |Q| = m\}$. We also define the union and intersection of all the subsystems present in Q as $V_{\cup}(Q) \equiv \bigcup_{A \in Q} A$ and $V_{\cap}(Q) \equiv \bigcap_{A \in Q} A$ respectively. Finally, the von Neumann entanglement entropy of the subsystem A is given by S_A . Then the N -partite information that we are interested in is de-

FIG. 12. This figure shows how the m – partite information varies with m showing the entanglement distribution among different number of outer-spins.

defined as

$$I_{\{A_N\}}^N = \left[\sum_{m=1}^N (-1)^{m-1} \sum_{Q \in \mathcal{B}_m(\{A\})} S_{V_U(Q)} \right] - S_{V_{\cap}(A_N)} \quad (76)$$

Studying these multi-partite informations one can understand the nature of the correlations present among the outer spins. Our study of this multi-partite information presented in the above Fig.(12) shows that the higher order multi partite informations decrease as you increase the order following a power law.

B. Entanglement properties of the multichannel Kondo fixed point

FIG. 13. This is a schematic diagram of (a) single channel and (b) two channel problem. S_d is the impurity spin. For more details refer to the text.

Apart from various thermodynamic properties of the local NFL, here we study the various entanglement signatures present in the ground state. We start with the Hamiltonian Eq.(53) where we are only taking the nearest neighbor real space hopping (t) where $t = 0$ case is the zero mode Hamiltonian of the multi-channel Kondo as shown in the Fig.13. In the single channel case the impurity (S_d) is talking to the spin degree of freedom at the real space origin ($\{1_\uparrow, 1_\downarrow\}$) of the unique conduction bath via a Hisenberg coupling. For 2 channel case the impurity is talking to 2 different origins of different conduction

channels ($\{1_\uparrow, 1_\downarrow\}$ and $\{2_\uparrow, 2_\downarrow\}$) and hopping connects to their nearest neighbor sites, for example $\{1_\uparrow, 1_\downarrow\}$ connects to $\{l_{1\uparrow}, l_{1\downarrow}\}$. Thus, for K channel case we are solving a problem with one spin $1/2$ degree of freedom and $2K$ electronic sites. As we increase the hopping strength t from zero to non-zero, the sites of the zero mode Hamiltonian starts to scatter with their respective nearest neighbor sites.

FIG. 14. This Figures shown the variation of impurity entanglement entropy EE_{imp} with the variation of the hopping strength t for three different channel cases, $K = 1, 2, 3$. In this case we have fixed $\alpha = 1$.

1. Impurity entanglement entropy

First, we are interested in the impurity entanglement entropy which is a measure of entanglement of the impurity with the rest. To do so we calculate the ground state of the Hamiltonian Eq.(53) $|\psi_g(t)\rangle$ followed by density matrix $\rho_g(t) = |\psi_g(t)\rangle\langle\psi_g(t)|$. Then we calculate the reduced density matrix by partial tracing the impurity $\rho_{imp}(t) = Tr_{imp}\rho_g(t)$. By diagonalizing the reduced density matrix $\rho_{imp}(t)$ we get the eigenvalues $\lambda_i(t)$ and the von-Neumann entanglement entropy $EE_{imp}(t) = -\sum_i \lambda_i(t) \log \lambda_i(t)$. As shown in the Fig.14 for all the three channel cases at low hopping strength t there is a plateau in the EE_{imp} measurement before it starts to decline with the further increase of hopping strength. At low $t \ll 1$ single channel has the higher impurity entanglement, which decreases by the increase of the channel number. On the other hand at high hopping strength value we see a different ordering of the impurity entanglement entropy. Higher the channel number slower the

fall of the EE_{imp} with the increase of t . This shows that, multiple channels protects the impurity better in terms of impurity entanglement entropy making the multi channel problem more robust against the single channel case.

Though the plateau value of the impurity entanglement entropy at low hopping strength is very close to each other for different channel cases, there is a distinct difference between them. For the single channel case, the impurity entanglement entropy varies smoothly with the increase of t from zero to nonzero value without any discontinuity. On the other hand for higher channels like $K = 2$ and $K = 3$ there is a discontinuity in the impurity entanglement entropy at $t = 0^+$.

FIG. 15. This figure show the variation of mutual information between the impurity spin and 1_{\uparrow} state with respect to the variation of the hopping strength t . For more details please refer to the text. In the figure above $\gamma = 0.2195$.

2. Intra-channel Mutual information

Here we are interested in calculating Mutual information between two Fock states in the ground state wavefunction as a function of the hopping strength t varying from 0 to non zero values. Mutual information between two subsystems A, B is defined as $MI(A : B) = S(A) + S(B) - S(A \cup B)$, where $S(A)$ is the von-Neumann entanglement entropy of the sub-system A with the rest of the system. To find out the entanglement present between two Fock states within a single channel, we calculate the intra-channel mutual information.

Case 1: First, we study the mutual information between the impurity spin S_d and 1_{\uparrow} Fock state (Fig.13) represented as $MI(d, 1_{\uparrow})$, where 1 is realspace origin of the 1^{st} conduction channel. For single channel case

this 1_{\uparrow} site can be chosen uniquely but for K channel cases there are K possible choices, due to the symmetry any one choice will show similar mutual information signature. Similarly due to the $SU(2)$ spin rotation symmetry the mutual information between the impurity spin and 1_{\downarrow} state will not be any different. We have numerically computed the variation of mutual information with respect to the hopping strength t and presented in the Fig.15. As shown in the inset of the Fig.15 at low hopping strength the mutual information for both the single channel and twochannel cases is saturating at different values. In the single channel case the Mutual information for $t = 0$ is $MI(d, 1_{\uparrow}) = \log 2$ and changes smoothly to nonzero t values, similar to the previous impurity entanglement entropy study (EE_{imp}).

$$S_d = S_{1_{\uparrow}} = S_{d, 1_{\uparrow}} = \log 2, \quad MI(d, 1_{\uparrow}) = \log 2 \quad (77)$$

This $\log 2$ value shows the stability of the zero mode of single channel and perfect screening. Next we focus to the two channel case where the mutual information is $MI(d, 1_{\uparrow}) = 0.2401$ which is less than the single channel case showing the breakdown of screening. Note, unlike the single channel case there is a discontinuity in $MI(d, 1_{\uparrow})$ at $t = 0^+$.

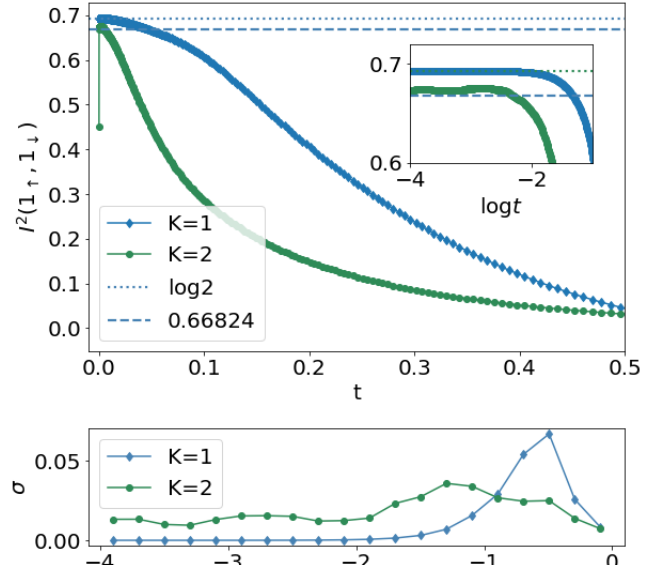

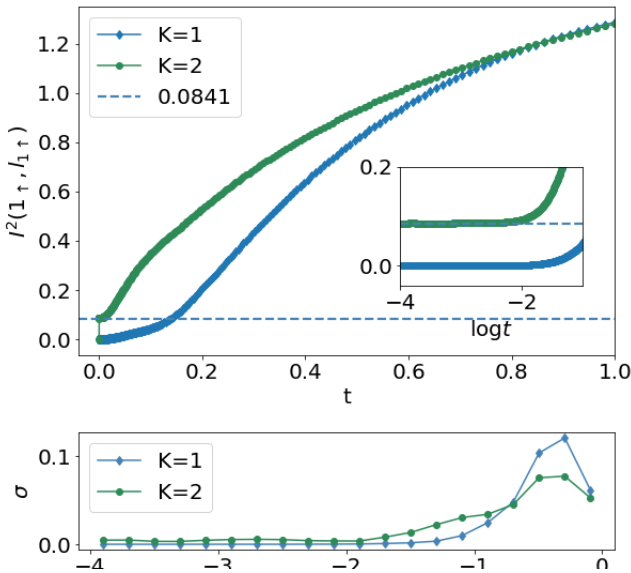

FIG. 16. This figure shows the variation of mutual information among the two fock states present on the realspace origin of a conduction channel with t . In the figure above $\delta = 0.450$

Case 2: Similarly we have computed the mutual information $MI(1_{\uparrow}, 1_{\downarrow})$ (Fig.16) which measures intra channel mutual information between two fock states $1_{\uparrow}, 1_{\downarrow}$ present at realspace origin. We find that the Mutual information is a smooth function of t for single channel and for two channel there is a discontinuity at $t = 0^+$. Note, $MI(1_{\uparrow}, 1_{\downarrow}) > MI(d, 1_{\uparrow})$ for all t values show the presence of stronger intra-site correlation.

FIG. 17. $MI(d, l_{1\uparrow})$

Case 3: Here we measure mutual information between the impurity and the Fock state of the nearest neighbor site to the realspace origin (Fig.13) of the conduction channel, $MI(d, l_{1\uparrow})$ as shown in the Fig.17. Vanishing mutual information for the single channel case shows the perfect screening of the impurity spin. On the other hand we expect the breakdown of screening in two channel case, which is confirmed by the non-zero value of mutual information at small t values. Here also we find a discontinuity in the mutual information at $t = 0^+$.

FIG. 18. $MI(1_{\sigma}, l_{1\sigma})$ FIG. 19. $MI(1_{\sigma}, 2_{\sigma'})$

Case 4: Another complementary study can be made by measuring the mutual information between conduction channel realspace origin and its nearest neighbor site to check their mutual entanglement. As shown in the Fig.18, we find that at low hopping strength the single channel mutual information vanishes showing the decoupling of those two states. On the other hand in the two channel case there is a non-zero mutual information which verifies the presence of active scattering between the local Mott liquid and the local non-Fermi liquid phases. Similar discontinuity in the mutual information was observed at $t = 0^+$.

All the above entanglement studies suggest that for two channel problem there is a discontinuity in the ground state at $t = 0^+$, whereas for the single channel case it is a smooth function. Thus for single channel case the $t = 0$ and $t \neq 0$ cases can be adiabatically connected, which is not the case for any other channel cases.

3. Inter-channel Mutual information

Apart from the intra-channel mutual information, here we study the mutual information between two channels to calculate the entanglement content within the local Mott liquid phase. In the Fig.19 above we study the mutual information $MI(1_{\sigma}, 1_{\sigma'})$ between two Fock states $1_{\sigma}, 1_{\sigma'}$ as shown in the Fig.13 for the two channel case. This shows that at low hopping strength there is a non-zero mutual information. This confirms the presence of correlation among channels. Apart from mutual information we have also computed the tripartite information across channels for this two channel case in the presence of non-zero hopping.

FIG. 20. Tripartite information TPI 156

4. Tripartite information

As shown in the result above Fig.20 the tripartite information has a discontinuity at $t = 0^+$. For small t values the presence of non-zero tripartite information signals the presence of tripartite correlation in the ground state which agrees with presence of Marginal Fermi liquid phase shown by the effective Hamiltonian study.

5. Bures distance and orthogonality catastrophe

Apart from different entanglement measures we have measured the Bures distance, which is a measure of distance between two density matrices. Which is defined as

$$d_{Bures}(\rho_1, \rho_2) = \sqrt{2} \left[1 - \text{Tr} \left\{ \left(\rho_1^{1/2} \rho_2 \rho_1^{1/2} \right)^{1/2} \right\} \right] \quad (78)$$

One can see from the above definition that, the maximum and minimum distance it can have is $\sqrt{2}$ and 0 respectively. This measure represents the distance between two states in a Hilbert space.

We get the ground state wavefunction of the problem by solving the Hamiltonian Eq.(53) $|\psi(t)\rangle$ which is a function of t and $\rho(t) = |\psi(t)\rangle\langle\psi(t)|$. We are interested in the reduced density matrix of the stargraph sites, to get that we partial trace out all other nearest neighbor sites, $\rho_{sg}(t) = \text{Tr}_{NN}(\rho(t))$. Then the Bures distance between the reduced density matrices $\rho_{sg}(t=0)$ and $\rho_{sg}(t)$, denoted as $d_{Bures}(\rho_{sg}(t=0), \rho_{sg}(t))$ are computed for single, two and three channel cases. We have shown the variation of the Bures distance as a function of the hopping strength in the Fig.21 above. For all three cases the

FIG. 21. Bures distance

Bures distance is zero at $t = 0$, which is obvious. But as you turn on t slightly there is a discontinuity in the distance for two and three channel cases against the single channel where the distance varies smoothly. This discontinuity in the higher channel case against the single channel is similar to all the above entanglement studies. The smooth variation of the distance in the single channel case shows the adiabatic continuation of the reduced stargraph density matrix from the $t = 0$ case to $t \neq 0$ case. On the other hand the abrupt jump in the Bures distance for higher-channel cases at $t = 0^+$ shows the breakdown of adiabatic continuity signaling an orthogonality catastrophe. Three channel case shows higher amount of discontinuity than the two channel case saturating at higher value for $t = 1$. Due to finite size system we cannot see the exact orthogonality by getting the $d_{Bures} = \sqrt{2}$, but higher channel cases with higher discontinuity suggests so.

VI. DUALITIES OF THE MULTI-CHANNEL KONDO MODEL

We start from a strong coupling ($J \rightarrow \infty$) spin- S impurity MCK Hamiltonian in the over-screened regime ($K > 2S$),

$$H(J) = \sum_{k,\sigma,l} \epsilon_{k,l} \hat{n}_{k\sigma,l} + J \vec{S}_d \cdot \vec{s}_{\text{tot}}. \quad (79)$$

Here, \vec{s}_{tot} is the total spin $\sum_l \sum_{kk'\alpha\beta} \vec{\sigma}_{\alpha\beta} c_{k\alpha,l}^\dagger c_{k'\beta,l}$ of all the zero modes. At strong coupling, the ground states of the star graph eq. 8 act as a good starting point for a perturbative expansion. As argued previously, there are $K - 2S + 1$ ground states, labeled by the K values

of the total spin angular momentum $S^z = S_d^z + s_{\text{tot}}^z = -\frac{K}{2} + S, -\frac{K}{2} + S + 1, \dots, \frac{K}{2} - S$. To leverage the large coupling, one can define a new spin impurity \mathbb{S} out of this ground state manifold. Since the degeneracy of a spin is given by its multiplicity $2S' + 1$, we have $2S' + 1 = K - 2S + 1 \implies S' = \frac{K}{2} - S$. That is, the spin- S impurity has a dual described by a spin- $(K - 2S + 1)$ impurity. The states of this new spin are defined by

$$\mathbb{S}_d^\pm |S^z\rangle = S^z |S^z\rangle, \quad \mathbb{S}_d^\pm |S^z\rangle = \sqrt{S'(S' + 1) - S^z(S^z \pm 1)} |S^z \pm 1\rangle \quad (80)$$

The excited states of the star graph can be used to define bosons [31], and the hopping into the lattice can then be re-written using these Bosons. One can then remove the single-particle hopping between the zero modes and the first sites using a Schrieffer-Wolff transformation in the small coupling $J' = \gamma \frac{4t^2}{J}$, and generate an exchange-coupling between the new impurity $\vec{\mathbb{S}}_d$ and the new zero modes formed out of the remaining sites in the lattice [31] (by remaining, we mean those real space sites that have not been consumed into forming the new spin). The new Hamiltonian, characterized by the small super-exchange coupling J' , has the form

$$H'(J') = \sum_{k,\sigma,l} \epsilon_{k,l} \hat{n}_{k\sigma,l} + J' \vec{\mathbb{S}}_d \cdot \vec{s}_{\text{tot}} \quad (81)$$

The prime on s_{tot} indicates that it is formed by the new zero modes. This Hamiltonian is very similar to the one in eq. 79, and that is the essence of the strong-weak duality: One can go from the over-screened strong coupling spin- S MCK model to another over-screened weak coupling spin- $(K - 2S + 1)$ MCK model. For the case of $K = 4S$, we have $S' = S$, and both S_d and \mathbb{S}_d describe the same spin objects (at least formally). The two models are then said to be self-dual. For example, for the case of spin-half MCK model, two-channel model is self-dual.

FIG. 22. Duality of the RG flows as seen in the star graph Hamiltonian. The red and green circles represent the impurity and zeroth site spins respectively. At large J , the red circle binds with the green circles to form an effective spin $\frac{K-1}{2}$ object (yellow) that interacts with the remaining spin of the conduction bath (blue circles).

One important consequence of the duality relationship between the two over-screened models is that the RG

equations are also dual; while the strong coupling model has an irrelevant coupling J that flows down to the intermediate fixed point J^* , the weak coupling model has a relevant coupling J' that flows up to the same fixed point $J'^* = J^*$. From the RG equation for the general spin- S MCK model, we know that $J'^* = \frac{2}{K\rho'}$, where ρ' is the DOS for the bath of the weak coupling Hamiltonian. This constrains the form of the scaling factor γ :

$$J'^* = \frac{\gamma 4t^2}{J^*} = \frac{2}{K\rho'} \implies \gamma = \frac{1}{4t^2} J^{*2} = \frac{1}{K^2 t^2 \rho \rho'} \quad (82)$$

There exists another set of dual points in the MCK model. This was hinted at when we looked at the degree of compensation in eq. 16. Since Γ depends only on the magnitude of δ , both $\pm\delta$ will give the same degree of compensation, same ground state energy and same ground state degeneracy ($g_K^S = |\delta| + 1$). The definition of δ gives the duality transformation as $K \rightarrow 2S, S \rightarrow \frac{K}{2}$. That is, we transform from a K -channel MCK model with spin- S impurity, to a $2S$ -channel MCK with a spin- $\frac{K}{2}$ impurity. The exactly-screened model $K = 2S$ maps on to itself and is therefore self-dual under this transformation.

For $K \neq 2S$, we transform an over-screened model into an under-screened model and vice versa. This duality relationship allows us to infer the RG scaling behaviour of one of the models if we know that of the other. If we know that for a certain pair of values K and S , the K -channel MCK model with spin- S impurity has an intermediate fixed point, we can immediately conclude that the $2S$ -channel spin- $\frac{K}{2}$ model has a strong coupling fixed point.

FIG. 23. ./duality2.pdf

VII. IMPURITY QUANTUM PHASE TRANSITION IN THE MULTI-CHANNEL KONDO MODEL UNDER CHANNEL ANISOTROPY

RADICALLY SHORTEN AND RESTRUCTURE THIS SECTION. SHOW THE NUMERICS FIRST, THEN SHOW THE RG EQUATION AND QUICKLY DISCUSS ITS CONSEQUENCES.

A. RG analysis

The isotropic MCK mode undergoes a phase transition when the symmetry of the channel interaction strengths is destroyed. We will now summarize the conclusions of this section. It will be shown analytically that if, in a K -channel model, one of the couplings becomes slightly larger than the other $K - 1$ couplings, the system goes into the singlet ground state characterized by local Fermi liquid excitations. On the other hand, if one of the couplings becomes slightly smaller than the rest, the system goes over to the $K - 1$ channel Kondo model. *This shows that in the context of the general anisotropic MCK model, the symmetric model is highly unstable under slight anisotropy, and undergoes a phase transition into either the $K - 1$ channel NFL phase or into the single channel LFL phase.*

FIG. 24. Transitions from one Kondo model to another under insertion of anisotropy. The green circles represents MCK models with $K > 1$ while the black circle represents the $K = 1$ model. The red lines indicate transition from the K channel MCK model to the single-channel model when one of the exchange couplings becomes larger than the others. The black lines indicate the transition from the K channel model to the $K - 1$ channel model when one of the exchange couplings becomes smaller than the others.

To see the transition, we need to start with the more general anisotropic MCK model:

$$H = \sum_{k,\alpha,l} \epsilon_{k,l} \hat{n}_{k\alpha,l} + \sum_{\substack{k,k',l \\ \alpha,\beta,l}} J_l \vec{S}_d \cdot \frac{1}{2} \vec{\sigma}_{\alpha\beta} c_{k\alpha,l}^\dagger c_{k'\beta,l} . \quad (83)$$

We now consider the specific case where $K - 1$ channels have the same coupling $J_1 = J_2 = \dots = J_{K-1} = J_+$ and the remaining channel has a different coupling $J_K = J_-$. The RG equations for such a model are

$$\frac{\Delta J_\pm}{|\Delta D|} = -\frac{J_\pm^2 \rho}{\mathcal{D}_\pm} + \frac{\rho^2 J_\pm}{2} \left[\frac{(K-1)J_+^2}{\mathcal{D}_+} + \frac{J_-^2}{\mathcal{D}_-} \right] \quad (84)$$

where $\mathcal{D}_\pm = \omega - \frac{D}{2} - \frac{J_\pm}{4}$ are the denominators of the URG equations. Setting $J_+ = J_-$ leads to the critical fixed point at $J_+^* = J_-^* = J_* = \frac{2}{K\rho}$. We now perturb around this fixed point by defining new variables $j_\pm = J_\pm - J_*$. We also assume that the bandwidth is large enough so that $\mathcal{D}_\pm \simeq \omega - \frac{D}{2} - \frac{J_*}{4} = -|\mathcal{D}_*|$. The RG equations then take the form

$$\frac{\Delta j_+}{|\Delta D|} = \frac{\rho J_+}{|\mathcal{D}_*|} \left[J_+ - \frac{\rho}{2} [(K-1)J_+^2 + J_-^2] \right] = \frac{\rho J_+}{K J_* |\mathcal{D}_*|} [-(K-2) J_* j_+ - (K-1) j_+^2 - j_-^2 - 2 J_* j_-] \quad (85)$$

$$\frac{\Delta j_-}{|\Delta D|} = \frac{J_- \rho}{|\mathcal{D}_*|} \left[J_- - \frac{\rho}{2} [(K-1)J_+^2 + J_-^2] \right] = \frac{J_- \rho}{K J_* |\mathcal{D}_*|} [(K-2) J_* j_- - j_-^2 - (K-1) j_+^2 - 2(K-1) J_* j_+] \quad (86)$$

$$(87)$$

We will first look at the special case of $K = 2$, the two channel Kondo model. The equations simplify to

$$\frac{\Delta j_\pm}{|\Delta D|} = \frac{J_\pm \rho}{K J_* |\mathcal{D}_*|} [-(j_+^2 + j_-^2) - 2 J_* j_\mp] \quad (88)$$

For $j_- < 0, j_+ > 0$, we have $\Delta j_- < 0$. The coupling J_- therefore becomes irrelevant. For small j_+ , we have $j_+^2 < 2 J_* |j_-|$ and $\Delta j_+ > 0$. This means that the isotropic fixed point is repulsive under anisotropy [1]. The coupling j_+ being relevant means we have a single-channel Kondo problem. We already know the non-perturbative URG equation for the single-channel Kondo problem [8], and it leads to the strong coupling fixed point [1, 24, 57].

We now look at the general K channel case. Let us first look at the regime $j_- < 0, j_+ > 0$. In this regime,

we have $\Delta j_- < 0$, which means j_- will flow to larger negative values until it reaches $j_- = -J_*$ such that $J_- = J_* + j_- = 0$. j_+ is, on the other hand, relevant for small values of j_\pm . It will continue to grow until the numerator of Δj_+ vanishes. This condition is given by

$$(K-2) J_* j_+ + (K-1) j_+^2 + j_-^2 + 2 J_* j_- = 0 \quad (89)$$

Substituting $j_- = -J_*$ gives the fixed-point equation $(K-1) j_+^2 + (K-2) J_* j_+ - J_*^2 = 0$. Solving the equation gives

$$j_{+,*} = \frac{J_*}{2(K-1)} [-(K-2) \pm K] = \frac{J_*}{K-1} \quad (90)$$

At the final step, we chose the positive solution, because j_+ is relevant in this regime. The new fixed point value

of J_+ is therefore

$$J_{+,*} = J_* + \frac{J_*}{K-1} = \frac{\frac{2}{K\rho}K}{K-1} = \frac{2}{(K-1)\rho} \quad (91)$$

In other words, the K channel fixed point flows to the $K-1$ channel fixed point. This is shown numerically in the left panel of fig. 25.

In the opposite regime $j_- > 0, j_+ < 0$, Δj_+ is negative. It has been checked numerically that J_+ ultimately flows to zero in this regime (middle and right panels of fig. 25), and J_- remains relevant. Since there is no numerator fixed point in the relevant coupling J_- and because all other couplings are irrelevant, the equation for J_- is replaced by the single-channel Kondo coupling URG equation, and the low-energy physics is then of strong coupling.

B. Channel anisotropy

So far we have talked the stargraph problem where all the outer spin is coupled with the central impurity spin with Heisenberg coupling of equal strength. This model has a special symmetry where any rearrangement of the outer spins keeps the stargraph Hamiltonian invariant. Here we wish to break this symmetry of this Hamiltonian by choosing the individual coupling strength of the outer spin with the central impurity spin different. We start with the general coupling Hamiltonian written as

$$H_K(\vec{\lambda}) = \sum_{i=1}^K \lambda_i \vec{S}_d \cdot \vec{S}_i \quad (92)$$

where $\vec{\lambda} \equiv (\lambda_1, \dots, \lambda_K)$ and $\lambda_i > 0, \forall i$. So far we have considered the case where $\lambda_i = \mathcal{J}, \forall i$. Numerical study of the Hamiltonian Eq.(92) shown that for any values of coupling $\lambda_i > 0$ the ground state degeneracy for a $S_d = 1/2$ is always K fold, where K is the number of channels. This shows the robustness of the ground state degeneracy of the stargraph model against the coupling anisotropy. The ground state degeneracy only changes when atleast one coupling vanishes or becomes infinite. In the case when one coupling of K channel anisotropic stargraph model vanishes, the effective model becomes a $K-1$ channel anisotropic stargraph model with $K-1$ fold degenerate ground states. On the other hand, if one of the K couplings becomes infinite then with respect to that coupling other couplings becomes zero thus giving rise to an effective single channel stargraph model. For example, for $\lambda_K \rightarrow 0$, the Hamiltonian becomes $H_K(\vec{\lambda}) \rightarrow H_{K-1}(\lambda_1, \dots, \lambda_{K-1})$ and for $\lambda_K \rightarrow \infty$ we get $H_K(\vec{\lambda}) \rightarrow H_1(\lambda_K)$.

We have demonstrated this numerically for a three channel anisotropic stargraph model. As shown in the Fig.26(a) where two couplings are same ($\lambda_1 = \lambda_2 = 1$) and we are numerically varying the third coupling λ_3

from finite to zero. The degeneracy is always 3 except when $\lambda_3 = 0$, then the degeneracy becomes 2 becoming an effective two channel problem. On the other hand in Fig.26(b) we keep the first coupling λ_3 fixed to 1 and vary the common coupling $\lambda_1 = \lambda_2$ from non-zero to zero, this is equivalent to keeping $\lambda_1 = \lambda_2 = 1$ fixed and taking λ_1 to infinity from finite. In this case we find when the coupling $\lambda_1 = \lambda_2 = 0$ the degeneracy becomes one showing the effective single channel nature.

FIG. 25. left panel: Flow of J_{\pm} when $j_{-} < 0$ and J_{+} . The smaller coupling J_{-} is irrelevant and switches off, while the other $K - 1$ couplings J_{+} flow to the $K - 1$ MCK fixed point. Middle and right panels: Flow of the couplings J_{+} when $j_{+} < 0$ when $j_{-} > 0, j_{+} < 0$, for two values of K . In both cases, the smaller coupling J_{+} eventually dies out, leading to only one surviving coupling J_{-} which is relevant, and we are left with a single-channel Kondo model.

In the URG analysis of the one dimensional Hubbard model [7], a study of the zero mode Hamiltonian (in that case, the Fermi surface itself) was sufficient to topologically characterize various phases of the Berezinskii-Kosterlitz-Thouless (BKT) RG phase diagram.
